

1

Basics

Functional Programming

Utrecht University

- Function definitions
 - Local definitions
 - Guards and pattern matching
- Working with tuples and lists
- Layout and comments
- Notions about types
 - What is *polymorphism*?

Chapters 4 (up to 4.4) and 3 from Hutton's book

From the previous lecture...

```
average ns = sum ns `div` length ns
```

- Function average and argument ns are in *lowercase*
- This line defines an *equation*
- Calling a function is done *without parentheses*
 - div is used as an operator

There are two ways to create a list:

- [] is the empty list
- Given an element x and a list xs, we can create a new list x : xs that starts with x and whose remaining elements are in xs.

```
> 1 : []
[1]
> 1 : [2,3]
[1,2,3]
```

• In fact, [1,2,3] is sugar for 1 : (2 : (3 : []))

Basic list functions

- null tells whether a list is empty
- · head returns the first element in a list
- tail returns all but the first element

```
> null [1,2,3]
False
> head [1,2,3]
1
> tail [1,2,3]
[2,3]
```

Basic list functions

- null tells whether a list is empty
- · head returns the first element in a list
 - · head fails if the list is empty
- tail returns all but the first element
 - tail fails if the list is empty

```
> null [1,2,3]
False
> head [1,2,3]
1
> head []
*** Exception: Prelude.head: empty list
> tail [1,2,3]
[2,3]
```

Types of the basic list functions

• What are the types of those functions?

Types of the basic list functions

• What are the types of those functions?

Here is the first one: null checks if a list is empty

null :: [a] -> Bool

```
What about head, tail, [], and (:)?
```

Types of the basic list functions

• What are the types of those functions?

```
Here is the first one: null checks if a list is empty
null :: [a] -> Bool
What about head, tail, [], and (:)?
head :: [a] -> a
tail :: [a] -> [a]
[] :: [a]
(:) :: a -> [a] -> [a]
```

```
if condition then expression else expression abs n = if n < 0 then -n else n
```

```
firstordefault def list
```

```
=
```

Conditionals

if condition then expression else expression

```
abs n = if n < 0 then -n else n
```

firstordefault def list

- = if null list then def else head list
- condition must be a Bool expression
- You always need **both** branches
 - What would you return if one is missing?
 - Remember, everything is an expression

Layout rule

- Haskell does not have other delimiters but parentheses
 - Not completely true, but valid for human-produced code
 - The grouping is done by indentation
- The layout rule applies for indentation
 - · Related elements must start on the same column
 - In the case of conditionals, no requirements

 abs n = if n < 0</td>
 abs n = if n < 0</td>

 then -n
 then -n

 else n
 else n

Instead of conditionals, we use equations with guards

- Each guard defines a condition over the arguments
- These conditions are checked in order
 - The first satisfiable one is applied
- We typically use otherwise for the default case

abs n | n < 0 = -n | otherwise = n

Nested conditionals versus guards

```
sign n = if n < 0
    then -1
    else if n == 0
    then 0
    else 1</pre>
```

What does this function do?

Nested conditionals versus guards

```
sign n = if n < 0
    then -1
    else if n == 0
    then 0
    else 1</pre>
```

What does this function do?

It reads much better with guards!

```
sign n | n < 0 = -1
| n == 0 = 0
| otherwise = 1
-- Why not | n > 0 = 1 ?
```

Good style Prefer guards overs conditionals

```
distance px py qx qy =
    sqrt ((px - qx)*(px - qx) + (py - qy)*(py - qy))
```

expression where name = expression

distance px py qx qy = sqrt (xDiff + yDiff)

where

```
xDiff = square (px - qx)
yDiff = square (py - qy)
square z = z * z
```

```
distance px py qx qy =
    sqrt ((px - qx)*(px - qx) + (py - qy)*(py - qy))
```

let name = expression in expression

```
distance px py qx qy =
  let xDiff = square (px - qx)
   yDiff = square (py - qy)
   square z = z * z
  in sqrt (xDiff + yDiff)
```

expression where name = expression

let name = expression in expression

- Local definitions assign a name to an expression
 - In the larger expression, this name is available
- Multiple benefits
 - Maintainability: reduce repetition of code
 - Performance: the expression is only computed once
 - Documentation: assign names to concepts

- You can have more than one local definition
 - Definitions may refer to each other
- The layout rule kicks in
 - All definition must start in the same column
 - Aligning ='s is not mandated, but good style

Let vs Where

- where when thinking top down
- let when thinking bottom up

Let vs Where

- where when thinking top down
- let when thinking bottom up
- let is an expression; where is not.

foo x = show (let $y = x^*x$ in y^*y) ++ " someString"

```
bar x | f x < 5 = undefined
    | f x == 5 = undefined
    | otherwise = undefined</pre>
```

where

f y = undefined

- Lists are sequences of elements of the same type
 - Unknown length, uniform type

[True, False] :: [Bool]

- Tuples are made of a number of components
 - Known length, different types

(True, 'a') :: (Bool, Char) (1, 'b', 3) :: (Int, Char, Int)

• Useful for returning several values

Tuple Examples

Creating tuples:

Tuple Examples

Creating tuples:

Extracting from tuples:

distance (px, py) (qx,qy) = sqrt (xDiff + yDiff)

where

```
tpl = squareBoth (px - qx, py - qy)
squareBoth (xD,yD) = (xD*xD, yD*yD)
```

```
xDiff = fst tpl
yDiff = snd tpl
```

Tuple Examples

Creating tuples:

```
remainder :: Double -> (Int,Double)
remainder x = let i = floor x
in (i, x - fromIntegral i)
```

Extracting from tuples:

```
distance (px, py) (qx,qy) = sqrt (xDiff + yDiff)
where
```

```
tpl = squareBoth (px - qx, py - qy)
squareBoth (xD,yD) = (xD*xD, yD*yD)
```

```
(xDiff, yDiff) = tpl
```

Comments

```
-- Euclidean distance between two points
distance (px, py) (qx, qy) =
    sqrt (xDiff + yDiff) -- some comment
where
    {- multi
    line comments are also
```

```
possible -}
```

- -- comments skip until the end of the line
- { comments skip until its matching }
 - Warning! These comments nest

From the previous lecture...

fac 0 = 1fac n = n * fac (n-1)

- The first equation is chosen if the arguments is 0
- Otherwise, the second branch is executed
- This is an example of **pattern matching**

- For a call replicate n x,
 - If n is 0, we return an empty list
 - Otherwise, we attach a copy of x to the result of replicating the element n-1 times

- For a call replicate n x,
 - If n is 0, we return an empty list
 - Otherwise, we attach a copy of x to the result of replicating the element n-1 times

```
replicate :: Int -> a -> [a]
replicate 0 x = []
replicate n x = x : replicate (n-1) x
```

- For a call replicate n x,
 - If n is 0, we return an empty list
 - Otherwise, we attach a copy of x to the result of replicating the element n-1 times

```
replicate :: Int -> a -> [a]
replicate 0 _ = []
replicate n x = x : replicate (n-1) x
```

• Good style: use _ if you don't care about a value

Pattern matching for lists and tuples

- · The syntax for construction can be used for matching
- Information is extracted by giving *names* to the parts
 - As usual, starting with lowercase

null [] = True null _ = False length [] = 0 length (_ : xs) = 1 + length xs

```
squareBoth (xD, yD) = (xD*xD, yD*yD)
```

Pattern matching, conjunction

• For Bools, we can list all the possible values

```
conj :: Bool -> Bool -> Bool
conj True True = True
conj True False = False
conj False True = False
conj False False = False
```

Pattern matching, conjunction

• For Bools, we can list all the possible values

```
conj :: Bool -> Bool -> Bool
conj True True = True
conj True False = False
conj False True = False
conj False False = False
```

- But this is very repetitive!
 - All last three equations return False

conj True True = True

- conj a b = False
- even better, use _ instead of a and b

Nested patterns

- · Instead of just giving a name, you can further pattern match in a list or tuple
 - You can go as deep as you want

trimstart (' ' : xs) = trimstart xs
trimstart ('\t' : xs) = trimstart xs
trimstart xs = xs
iszero (0, 0) = True
iszero _ = False
sumifthree (a : b : c : []) = a + b + c

```
sumifthree _ = 0
```

```
length xs | xs == [] = 0
| otherwise = 1 + length (tail xs)
```

Two problems with this definition:

```
length xs | xs == [] = 0
| otherwise = 1 + length (tail xs)
```

Two problems with this definition:

- == is more expensive than matching
- You need to call tail

Good style for defining a function

- Pattern matching, maybe with guards
 - But **not** guards with ==

```
length xs | xs == [] = 0
| otherwise = 1 + length (tail xs)
```

The correct way to write length is:

length [] = 0
length (_ : xs) = 1 + length xs

- Substitute check of [] by pattern matching
- Access the tail of the list by matching (_ : xs)

existsPositive xs should return True if and only if (at least) one of the elements in the list xs is positive, that is, greater than 0

existsPositive xs should return True if and only if (at least) one of the elements in the list xs is positive, that is, greater than 0

```
existsPositive [] = False
existsPositive (x:xs) | x > 0 = True
| otherwise = existsPositive xs
```

existsPositive xs should return True if and only if (at least) one of the elements in the list xs is positive, that is, greater than 0

existsPositive [] = False existsPositive (x:xs) = x > 0 || existsPositive xs

Next lecture is devoted to functions over lists

From the previous lecture...

- Operators are functions whose name is exclusively made out of symbols
- Operators are written *between* the arguments
 - Both for definition and call

True && True = True _ && _ = False

• Anywhere else, you need to use parentheses

```
(&&) :: Bool -> Bool -> Bool
```

How should we read the following expressions?

1 + 2 - 3 1 * 2 + 3 / 4

We make it explicit by introducing parentheses

1 + (2 - 3) (1 * 2) + (3 / 4)

• We say that + *associates to the left*

• So 1 + 2 + 3 means (1 + 2) + 3

• We say that * and / have higher precedence than +

infixr/infixl/infix precedence operator

- infixr and infixl declare associativity
- infix makes the operator **non**-associative
 - == and /= are examples of those
- Precedence ranges between 1 and 9
 - Function application has the highest number, 10

infixr 3 &&

Types

Expressions have types

Type = collection of related values

- In Haskell, every *expression* has a *type*
- We write it as expression :: type

True :: Bool
'a' :: Char
[1, 2] :: [Int]
(1,'a') :: (Int,Char)
not :: Bool -> Bool

• This includes applied functions

1 + 2 :: Int not True :: Bool

Static typing and type safety

- · Haskell forbids executing code with type errors
 - This is known as *static* typing
 - Other languages are dynamically typed
 - E.g., Python, JavaScript, Ruby...
- As a result, no run-time error may arise from this
 - We say that Haskell programs are *type safe*
- · Some "valid" expressions are rejected
 - Code execution is not taken into account

if True then 1 else False

Type checking and inference

General rule: if f :: A -> B and e :: A, then f e :: B

This rule can be used in two ways:

• To check whether an application is correct

not :: Bool -> Bool

```
'a' :: Char
```

```
not 'a'
```

-- Couldn't match expected type 'Bool'

with actual type 'Char'

• To *infer* the result of an expression

```
f :: Bool -> String
```

f True :: String -- No further details needed!

Basic types

- Bool: logical values, that is, either True of False
- Char: single characters like 'a'
- Integral types:
 - Int: machine integers with a fixed range
 - > maxBound :: Int
 - 9223372036854775807
 - Integer: integers with unlimited range
- Floating-point types:
 - · Numbers with a decimal comma
 - Float: single-precision
 - Double: double-precision, take up more space

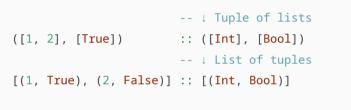

These types are parametrized by other types

- Lists [T], uniform sequences of Ts
- Tuples come in different *arities*
 - Pairs (T1, T2)
 - Triples (T1, T2, T3)
 - ... up to 62 in GHC 8.0.1
- Functions T1 -> T2 -> ... -> R

Types can be nested as much as we want

([1, 2], [True])

[(1, True), (2, False)]

```
-- ↓ Tuple of lists
([1, 2], [True]) :: ([Int], [Bool])
-- ↓ List of tuples
[(1, True), (2, False)] :: [(Int, Bool)]
f :: (Int, Int) -> Int
```

g :: Int -> Int -> Int

Some differences

```
--\downarrow Tuple of lists
([1, 2], [True]) :: ([Int], [Bool])
                         -- \downarrow List of tuples
[(1, True), (2, False)] :: [(Int, Bool)]
f :: (Int, Int) -> Int -- Takes one argument
                         -- which is a pair
g :: Int -> Int -> Int -- Takes two arguments
> f (1, 2) -- OK
> q 1 2 -- OK
> q (1, 2)
-- Couldn't match expected type 'Int'
               with actual type '(Int, Int)'
- -
```

Some differences

```
--\downarrow Tuple of lists
([1, 2], [True]) :: ([Int], [Bool])
                         -- \downarrow List of tuples
[(1, True), (2, False)] :: [(Int, Bool)]
f :: (Int, Int) -> Int -- Takes one argument
                         -- which is a pair
g :: Int -> Int -> Int -- Takes two arguments
> f (1, 2) -- OK
> q 1 2 -- OK
> q (1, 2)
-- Couldn't match expected type 'Int'
               with actual type '(Int, Int)'
- -
```

```
-- Functions can be put in a list
[(+), (*), (-)] :: [Int -> Int -> Int]
[(&&), (||)] :: [Bool -> Bool -> Bool]
```

```
-- Elements must agree in their type [(+), (&&)] -- Type error!
```

```
-- Functions can be arguments and results
-- 'flip' takes one function and swaps the order
flip :: (a -> b -> c) -> (b -> a -> c)
```

 length [1, 2, 3]
 -- 0K

 length [True, False]
 -- 0K

 length "abcd"
 -- 0K

- length can be applied to any expression which is a list
 - In type terms, to any [T], regardless of T
 - We say that length is **polymorphic**
 - From Greek, Πολυμορφισμός "of many forms/shapes"
- How does this show up in the type?

length :: [a] -> Int

- Types starting with lowercase are variables
- · They can be substituted with whatever we need

null :: [a] -> Bool
(++) :: [a] -> [a] -> [a] -- Concatenation
reverse :: [a] -> [a]

Important! A variable has to be substituted uniformly throughout the whole type

```
[1, 2] ++ [3, 4] :: [Int]
-- OK, 'a' is substituted by 'Int'
```

[1, 2] ++ [True, False]
-- Couldn't match expected type 'Int'
-- with actual type 'Bool'
This is the #1 type error in Haskell programming

id x = x

What is the type of id?

id x = x

What is the type of id?

- 1. It is a function with one argument
 - + $\,\alpha \rightarrow \beta$ for yet unknown α and β
- 2. We return the same type we are given
 - + $\alpha
 ightarrow \alpha$ for a yet unknown type α
- 3. There are no further constraints for x
 - We reach the final type a -> a
 - This function works for any type

Inferring the type of map id

Expect these kind of problems in the exam

map id :: ?

Inferring the type of map id

Expect these kind of problems in the exam

map id :: ?

1. Disambiguate the names of the type variables

• map :: (a -> b) -> [a] -> [b]

• id :: c -> c

2. If f :: A -> B, in f e we must have e :: A

- In this case, the type a -> b must be the same as the type c -> c, and
- thus type a must be type c and type b must also be the same as type c.
- Thus, map, in map id, has type (c -> c) -> [c] -> [c]
- 3. The result type of f e is B
 - In this case, map id :: [c] -> [c]

id id :: ?

id id :: ?

- 1. Disambiguate the names of variables for each id
 - Firstid :: a -> a
 - Secondid :: b -> b
- 2. If f :: A -> B, in f e we must have e :: A
 - In this case, a -> a must be b -> b
 - Thus, first id :: (b -> b) -> (b -> b)
- 3. The result type of f e is B
 - In this case, id id :: b -> b

```
> :t sin
sin :: Float -> Float
> :t [sin, id]
[sin,id] :: [Float -> Float]
```

- 1. We can choose any type for the a in id
- 2. All elements in a list must have the same type
- 3. The only solution is to make a be Float

What about these?

- > :t [length, head]
- > :t [head, null]
- > :t [tail, null]

What about these?

- > :t [length, head]
- > :t [head, null]
- > :t [tail, null]

```
> :t [length, head]
[length,head] :: [[Int] -> Int]
> :t [head, null]
[head,null] :: [[Bool] -> Bool]
> :t [tail, null]
Couldn't match type '[a]' with 'Bool'
```

Overloaded addition

In Haskell, addition works for different types:

```
> 1 + 2 -- Integers
3
> 1.0 + 2.5 -- Floating-point
3.5
```

But not for any type!

> 'a' + 'b'

No instance for (Num Char) arising from a use of '+'

Overloaded addition

Addition cannot be given the following type

(+) :: a -> a -> a

because it does not work for any type.

Overloaded addition

Addition cannot be given the following type

(+) :: a -> a -> a

because it does not work for any type.

Let's ask GHC what is its real type:

> :t (+)

(+) :: Num a => a -> a -> a

- The Num a before the => symbol is a constraint
- It restricts (+) to types which satisfy the constraint
 - In this case a must be "numeric"
- Num is called a type class
 - Warning! Not to be confused with C++/C#/Java classes

- Num for numeric types
 - Includes (+), (*), abs, among others
- For example, Int, Integer, Float, and Double have Num instances.
- Char or [Int] are not numeric

Basic type classes

- Num for numeric types
- · Eq for types which support equality checks

(==) :: Eq a => a -> a -> Bool -- Equals
(/=) :: Eq a => a -> a -> Bool -- Not equals

- Int, Char, Bool, ..., have Eq instances
- Also [T] if T is itself a member of Eq
 - Like [Int] or String
- But not function types

```
> sin == cos
No instance for (Eq (Float -> Float))
```

- Num for numeric types
- Eq for types which support equality checks
- Ord for types which in addition have an ordering

(<), (>) :: Ord a => a -> a -> Bool
(<=), (>=) :: Ord a => a -> a -> Bool
min, max :: Ord a => a -> a -> a

- Int, Char, Bool, .., have Ord instances
- Every type which is Ord is also Eq

- Num for numeric types
- Eq for types which support equality checks
- Ord for types which in addition have an ordering
- Show for turning things into strings

```
show :: Show a => a -> String
```

```
age :: Int -> String
age y = "You are " ++ show y ++ " years old"
```

- Almost everything is in Show, but not functions
- We need a explicit call to show to preserve type safety

- Num for numeric types
- Eq for types which support equality checks
- Ord for types which in addition have an ordering
- Show for turning things into strings
- And many more!

You can also define your own (later in the course)

```
> isZero x = x = 0
```

```
<interactive>:1:14: error:
```

```
parse error on input '='
```

Parse error = code does not follow the *syntax*

- The structure of the code cannot be understood
 - In this case, where does the real definition start?
- Parsing happens before typing
- · Check the shape and the upper/lowercase distinction

```
> isZero x = x = 0
```

```
<interactive>:1:14: error:
```

```
parse error on input '='
```

Parse error = code does not follow the *syntax*

- The structure of the code cannot be understood
 - In this case, where does the real definition start?
- Parsing happens before typing
- · Check the shape and the upper/lowercase distinction

> isZero x = x == 0

- Every expression has a type
- Types are used in two different ways
 - Checking that types match
 - Inferring a type for an expression
- Two forms of *polymorphism*
 - Functions that work for any type, parametric
 - Functions that work for a subset of types, *ad-hoc*

Check exercises at the end of chapter 3 of Hutton's book
